

A

Robustness to unmeasured confounding (E-value)

How strong an unmeasured confounder — associated (risk ratio) with both morphology and severity — would need to be to render each result non-significant. Farther from 1 = more robust.

B

High-grade Hunt & Hess by size-ratio tertile

C

If patients with missing grades were sicker

The size-ratio association stays essentially unchanged

A, E-value (95% CI limit) per FDR-significant association; for scale, the smoking-lung-cancer E-value is ≈ 10 .
B, Complete-case proportions for size ratio ($n = 133$); error bars, 95% CI. C, Missing-not-at-random sensitivity; multiple-imputation estimate, error bars 95% CI.
